Abstract

Determining a prior probability function via the maximum entropy principle can be a computationally intractable task. However one can easily determine — in advance of entropy maximisation — a list of probabilistic independencies that the maximum entropy function will satisfy. These independencies can be used to reduce the complexity of the entropy maximisation task. In particular, one can use these independencies to construct a directed acyclic graph in a Bayesian network, and then maximise entropy with respect to the numerical parameters of this network. This can result in an efficient representation of a prior probability function, and one that may allow efficient updating and marginalisation. The computational complexity of maximising entropy can be further reduced when knowledge of causal relationships is available. Moreover, the proposed simplification of the entropy maximisation task may be exploited to construct a proof theory for probabilistic logic.

1 Introduction

Bayesians argue that an agent's degrees of belief ought to respect the axioms of probability: a belief function ought to be a probability function. Many Bayesians impose further mechanisms for choosing a belief function, given an agent's background knowledge. In particular, many accept the *maximum entropy principle*, which says that one ought to adopt, out of all the probability functions that satisfy the constraints imposed by background knowledge, a function p that maximises entropy

$$H = -\sum_v p(v) \log p(v) \tag{1}$$

(where the sum is taken over the assignments v to elements of the domain — the notation will be explained in §2). This principle is often justified on the grounds that a maximum entropy probability function is a *least prejudiced* probability function that satisfies the constraints. It satisfies the constraints but commits to as little as possible beyond the knowledge embodied by the constraints.[1] A second justification cites a number of intuitively plausible conditions that any principle for determining a probability function from background knowledge ought to satisfy, and goes on to show that the maximum entropy principle is the only principle which satisfies these conditions.[2] The maximum entropy principle is still a matter of some controversy,[3] but I shall not dwell on the issue of justification any further here.

The chief difficulty for those who do accept the maximum entropy principle is that the number of parameters $p(v)$ in the entropy expression (Equation 1) is exponential in the size of the domain (see §3), so when the domain size is large it can be impractical to determine the values of the parameters that maximise entropy. The object of this paper is to put forward a principled and practical way of reducing the number of parameters required in the entropy maximisation process.

The key idea is this. By analysing the structure of the constraints imposed by background knowledge, it is possible to determine a host of conditional probabilistic independencies that the maximum entropy probability function p will satisfy. In §4 we shall see that the independence structure of p is most naturally represented by a Markov network. By transforming this Markov network into a Bayesian network (§5), we can exploit these independencies to reparameterise the entropy expression, thereby reducing the computational complexity of the maximisation task.[4]

[1] [Jaynes 1957].

[2] [Paris & Vencovská 2001].

[3] See [Halpern & Koller 1995], [Paris & Vencovská 1997].

[4] The fact that a maximum entropy probability function induces a range of probabilistic independencies is already an established part of the folklore in this field. Moreover, some practical proposals for maximising entropy aim to take advantage of these independencies: see for example [Rhodes & Garside 1995] which deals with independencies representable by binary trees, and www.pit-system.de

Apart from simplifying the entropy maximisation problem, exploiting the independencies inherent in the maximum entropy function yields the following advantages. First, we are left with a Bayesian network representation of an agent's belief function: this is desirable in that it may allow efficient storage and updating of the belief function (§5). Second, the approach allows further computational savings when the background knowledge includes knowledge of conditional independencies or causal relationships (§6). Third, the approach can be extended to cope with reasoning in domains which have logical as well as probabilistic structure (§7).

2 Framework and Notation

We shall be concerned with a finite domain $V = \{V_1, \ldots, V_n\}$ of discrete variables. Each variable V_i can take one of $||V_i|| \in \mathbb{N}_{>0}$ possible values, and the expression $v_i@V_i$ signifies that v_i is the assignment of V_i to one of its values. For a subset $U = \{V_{i_1}, \ldots, V_{i_k}\}$ of V, an assignment $u@U$ consists of an assignment to each of the variables in U, and u may be written $v_{i_1} \ldots v_{i_k}$, where $v_{i_1}@V_{i_1}, \ldots, v_{i_k}@V_{i_k}$. Thus upper-case letters refer to variables or sets of variables, while the corresponding lower-case letters refer to their assignments. Two assignments $u_1@U_1$ and $u_2@U_2$ are *consistent*, written $u_1 \sim u_2$, if they agree on $U_1 \cap U_2$. The number of variables in U is denoted by $|U|$, while $||U||$ refers to the number of assignments to U; clearly $||U|| = \prod_{V_i \in U} ||V_i||$.

A probability function p over V is determined by its values on the parameters $x^v =_{df} p(v)$, where v ranges over the assignments to V.[5] Each $x^v \in [0, 1]$ and by additivity of probability $\sum_{v@V} x^v = 1$. Given some fixed ordering of assignments to V, let x denote the vector of parameters $(x^v)_{v@V}$. The set of probability functions then corresponds to the space $\mathbb{P} = \{x \in [0, 1]^{||V||} : \sum_{v@V} x^v = 1\}$.

An agent's background knowledge is assumed to impose a number of constraints $\chi_1, \ldots, \chi_m$ on the set of probability functions that she may adopt. Associated with each constraint χ_i is the set C_i of variables involved in the constraint: if, for example, χ_i is the constraint that the mean of variable V_1 is $1/3$ then the associated constraint set is $C_i = \{V_1\}$. Let $z_i^{c_i} =_{df} p(c_i)$ where $c_i@C_i$, and let z_i be the vector of these parameters. Each constraint χ_i on C_i will be assumed to be an equality constraint of the form $f_i(z_i) = 0$ or an inequality constraint of the form $f_i(z_i) \geq 0$, for some function f_i (no restrictions are placed on the form of this function). Note that z_i is determined by x through the relationship $z_i^{c_i} = \sum_{v@V, v \sim c_i} x^v$. Denote the set of

which deals with linear constraints. The techniques of the present paper can be thought of as an extension of this line of work. Here we strive to capture as many induced independencies as possible, to represent these independencies in a natural and perspicuous way, and to avoid restrictions on the form or nature of the constraints.

[5] [Paris 1994] pp. 13-14.

constrained probability functions by $\mathbb{C}$, so

$$\mathbb{C} = \{x \in \mathbb{P} : f_1(z_1) \geqq 0, \ldots, f_m(z_m) \geqq 0\},$$

where $\geqq$ is either $\geq$ or $=$ according to the constraint. We shall assume throughout that the constraints $\chi_1, \ldots, \chi_m$ are consistent in the sense that $\mathbb{C} \neq \emptyset$, since maximising entropy subject to inconsistent constraints is trivial.

3 Maximising Entropy

Under the above x-parameterisation, the entropy equation is

$$H = -\sum_{v@V} x^v \log x^v \tag{2}$$

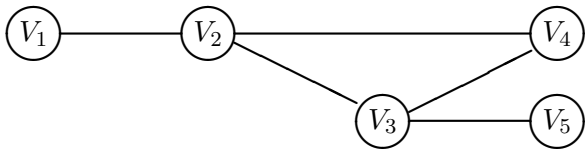
The maximum entropy principle requires that a parameter vector $x \in \mathbb{C}$ be found that maximises H. Typically one might use numerical methods such as gradient ascent to adjust the x^v until a local maximum is found or one might determine a local maximum by using the method of Lagrange multipliers. One needs of course to be wary of the following possibilities: (i) there may be no global maximum (although if the constraints limit x to a closed subset $\mathbb{C}$ of $\mathbb{P}$, then a global maximum will exist); (ii) there may be more than one global maximum (in which case Bayesians may deem the agent in question to be rational whichever global maximum she chooses as her belief function); (iii) the above methods may find a local maximum that is not the global maximum (note that there are no non-global maxima if $\mathbb{C}$ is convex, which occurs for example if the constraint functions f_i are all linear[6]).

Perhaps the most serious difficulty is this. There are $\prod_{i=1}^{n} ||V_i||$ assignments to V. One of the x-parameters is determined by additivity from the others, and so there are $(\prod_{i=1}^{n} ||V_i||) - 1$ free x-parameters, a number exponential in n. This is a problem for numerical methods because as n becomes large there will quickly become too many parameters to be stored and adjusted, and there may even be too many terms in Equation 2 to be summed in available time. Lagrange multiplier methods suffer analogously: a system of equations (consisting of the m constraint equations and $\prod_{i=1}^{n} ||V_i||$ partial derivatives of the Lagrange equation with respect to the x-parameters) must be solved for x, and this system of equations will quickly become unhandleable as n increases.

Unfortunately there appears to be no fully general solution to the complexity problem: the task of finding an approximation to the maximum entropy function is NP-complete[7] and the task of finding a likely approximation is RP-complete,[8] and so if NP $\neq$P $\neq$ RP then

[6] [Paris 1994] Proposition 6.1.
[7] [Paris 1994] Theorem 10.6.
[8] [Paris 1994] Theorem 10.7.

Figure 1: Example constraint graph



there is no polynomial time algorithm for performing these tasks and any algorithm will be intractable in the worst case as n increases. The best we can hope for is an algorithm which performs well on the type of problem that occurs in practice and badly only rarely. This at least would be an improvement on naive numerical and Lagrange multiplier approaches which perform uniformly badly.

The approach outlined in the rest of this paper is based on the premise that in practice the sizes of the constraint sets C_i are usually small in comparison with n, as n becomes large. Constraints often consist of observed means of single variables, marginals of small sets of variables, hypothesised deterministic connections amongst small sets of variables, causal connections amongst pairs of variables, independence relationships amongst small sets of variables, and so on. The point is that there is a limit to the amount we normally observe and to the connections amongst variables posited by background knowledge, in that while there may be many observations and many connections, each observation and connection will relate only few variables. The number of possible observations pertinent to a joint distribution over V increases exponentially with n, but, I suggest, our ability to observe increases sub-exponentially.

If such an assumption is correct, then as n grows there are many conditional independencies that the entropy-maximising probability function p will satisfy. We can identify these independencies just from the constraint sets C_i, and exploit them to simplify the task of determining p, as we shall now see.

4 From Constraints to Markov Network

Define an undirected *constraint graph* $\mathcal{G}$ as follows. Take as vertices the variables in V. Include an edge between two variables $V_i, V_j \in V$ if and only if V_i and V_j occur in the same constraint set C_k.

Suppose, for example, that $V = \{V_1, \ldots, V_5\}$ and that there are four constraints $\chi_1, \ldots, \chi_4$ constraining $C_1 = \{V_1, V_2\}, C_2 = \{V_2, V_3, V_4\}, C_3 = \{V_3, V_5\}, C_4 = \{V_4\}$ respectively. Then the constraint graph $\mathcal{G}$ is depicted in Figure 1.

The constraint graph is useful because it represents conditional independencies that a maximum entropy function p satisfies. This is best explained with the help of some additional terminology. Given disjoint $X, Y, Z \subseteq V$, we shall write $X \perp\!\!\!\perp_p Y \mid Z$ if, according to a

probability function p, X is probabilistically independent of Y conditional on Z, and we shall write $X \rightleftharpoons_p Y \mid Z$ if this independence does not hold, i.e. if X and Y are probabilistically dependent conditional on Z. We say that Z *separates* X from Y in undirected graph $\mathcal{G}$ if every path from a vertex in X to a vertex in Y goes through some vertex in Z.

Theorem 4.1 If Z separates X from Y in the constraint graph $\mathcal{G}$ then $X \perp\!\!\!\perp_p Y \mid Z$ for any p satisfying the constraints which maximises entropy.

Proof: The first step is to use standard Lagrange multiplier optimisation. By theorems of Lagrange and Runge-Kutta,[9] if $x \in \mathbb{C}$ is a local maximum of H then there are constants $\mu, \lambda_1, \ldots, \lambda_m \in \mathbb{R}$, called *multipliers*, such that

$$\frac{\partial H}{\partial x^v} + \mu + \sum_{i=1}^{m} \lambda_i \frac{\partial f_i}{\partial x^v} = 0 \tag{3}$$

for each assignment $v@V$, where μ is the multiplier corresponding to the additivity constraint $\sum_{v@V} x^v = 1$, and where $\lambda_i = 0$ for each inequality constraint which is not effective at x (i.e. for each inequality constraint χ_i such that $f_i(x) > 0$).

Now the argument of f_i is the vector z_i of probabilities of assignments to C_i. Moreover, $z_i^{c_i} = \sum_{v@V, v \sim c_i} x^v$, so

$$\frac{\partial f_i}{\partial x^v} = \frac{\partial f_i}{\partial z_i^{c_i}} \frac{\partial z_i^{c_i}}{\partial x^v} = \frac{\partial f_i}{\partial z_i^{c_i}}.1$$

where c_i is the assignment to C_i that is consistent with v. Furthermore,

$$\frac{\partial H}{\partial x^v} = -1 - \log x^v,$$

so Equation 3 can be written

$$\log x^v = -1 + \mu + \sum_{i=1}^{m} \lambda_i \frac{\partial f_i}{\partial z_i^{c_i}}$$

where each $c_i \sim v$. Thus,

$$x^v = e^{\mu - 1} \prod_{i=1}^{m} e^{\lambda_i \frac{\partial f_i}{\partial z_i^{c_i}}} \tag{4}$$

Hence the local maximum x is representable as a product of functions, each of which depends only on variables in a single constraint set C_i (the leading term is a constant). The probability function p corresponding to x is said to *factorise* according to the constraint sets $C_1, \ldots C_m$, and since these sets are complete subsets of $\mathcal{G}$, p is said to

[9] See for example [Sundaram 1996], Theorems 5.1 and 6.1.

factorise according to $\mathcal{G}$.[10] The *global Markov condition* says that if Z separates X from Y in $\mathcal{G}$ then $X \perp\!\!\!\perp_p Y \mid Z$, and this condition is a straightforward consequence of factorisation according to $\mathcal{G}$.[11] Thus the theorem follows for local maxima p, and in particular for global maxima p. ■

The converse does not hold in general. For example, a constraint χ_1 that asserts the independence of V_1 and V_2 must of course be satisfied by the maximum entropy function p, but would not correspond to any separation in the constraint graph $\mathcal{G}$. However, there is a partial converse to Theorem 4.1: separation in $\mathcal{G}$ captures all the conditional independencies of p that are due to structure of the constraint sets and not the constraints themselves. More precisely, suppose that as before we are given disjoint $X, Y, Z \subseteq V$ and constraint sets $C_1, \ldots, C_m$ and we construct the corresponding constraint graph $\mathcal{G}$; then

Theorem 4.2 If, for all $\chi_1, \ldots, \chi_m$ constraining $C_1, \ldots, C_m$ respectively, $X \perp\!\!\!\perp_p Y \mid Z$ where p is a function satisfying $\chi_1, \ldots, \chi_m$ that maximises entropy, then Z separates X from Y in $\mathcal{G}$.

Proof: We shall show the contrapositive, namely that if Z does not separate X from Y in $\mathcal{G}$ then there is some $\chi_1, \ldots, \chi_m$ constraining $C_1, \ldots, C_m$ such that, for p a maximum entropy satisfier of $\chi_1, \ldots, \chi_m$, $X \rightleftharpoons_p Y \mid Z$.

So suppose $V_{i_1}, \ldots, V_{i_k}$ is a shortest path from some $V_{i_1} \in X$ to some $V_{i_k} \in Y$ avoiding vertices in Z. The task is then to find some $\chi_1, \ldots, \chi_m$ that render V_{i_1} and V_{i_k} probabilistically dependent conditional on Z for the maximum entropy p.

For $j = 1, \ldots, k-1, V_{i_j}$ and $V_{i_{j+1}}$ are connected by an edge in $\mathcal{G}$, so they are in the same constraint set, which we can call C_j without loss of generality. Moreover no three vertices on the path are in the same constraint set, for we could otherwise construct a shorter path from V_{i_1} to V_{i_k} avoiding Z. Thus $C_1, \ldots, C_{k-1}$ are distinct. For each such constraint set C_j let χ_j consist of the constraint $p(v^*_{i_j} | v^*_{i_{j+1}}) = 1$ for some distinguished assignments $v^*_{i_j}, v^*_{i_{j+1}}$ to $V_{i_j}, V_{i_{j+1}}$ respectively. Moreover add the constraint $p(v^*_{i_1}) = 1/2$ to χ_1, by writing χ_1 as $(p(v^*_{i_1} | v^*_{i_2}) - 1)(p(v^*_{i_1}) - 1/2) = 0$. (It is straightforward to see that each χ_j can be written in the form $f_j(z_j) = 0$.) Let all other constraints $(\chi_k, \ldots, \chi_m)$ be vacuous. The constraints $\chi_1, \ldots, \chi_m$ thus defined are clearly consistent, and constrain $C_1, \ldots, C_m$ respectively.

Note that by rewriting the constraints $\chi_1, \ldots, \chi_{k-1}$ and discarding the vacuous constraints $\chi_k, \ldots, \chi_m$, one can repose the optimisation problem as one involving constraint sets $C'_1, \ldots, C'_{k-1}$ where $C'_j = \{V_{i_j}, V_{i_{j+1}}\}$ for $j = 1, \ldots, k-1$. These constraint sets lead to a constraint graph $\mathcal{G}'$ in which the only edges are those between V_{i_j}

[10] [Lauritzen 1996] 34-35.

[11] [Lauritzen 1996] Proposition 3.8.

and $V_{i_{j+1}}$ for $j = 1, \ldots, k-1$. By applying Theorem 4.1 to $\mathcal{G}'$, we see that $V_{i_j} \perp\!\!\!\perp_p \{V_{i_{j+2}}, \ldots, V_{i_k}\} \mid V_{i_{j+1}}$ for $j = 1, \ldots, k-2$, and (since none of $V_{i_1}, \ldots, V_{i_k}$ are in Z) $V_{i_1} \perp\!\!\!\perp_p Z \mid V_{i_k}$ and $V_{i_1} \perp\!\!\!\perp_p Z$. So for any $z@Z$,

$$\begin{aligned} p(v^*_{i_1}|v^*_{i_k}z) &= p(v^*_{i_1}|v^*_{i_k}) \\ &= \sum_{v_{i_2},\ldots,v_{i_{k-1}}} p(v^*_{i_1}|v_{i_2}\ldots v_{i_{k-1}}v^*_{i_k})p(v_{i_2}|v_{i_3}\ldots v_{i_{k-1}}v^*_{i_k})\ldots \\ &\quad \ldots p(v_{i_{k-2}}|v_{i_{k-1}}v^*_{i_k})p(v_{i_{k-1}}|v^*_{i_k}) \\ &= \sum_{v_{i_2},\ldots,v_{i_{k-1}}} p(v^*_{i_1}|v_{i_2})p(v_{i_2}|v_{i_3})\ldots \\ &\quad \ldots p(v_{i_{k-2}}|v_{i_{k-1}})p(v_{i_{k-1}}|v^*_{i_k}) \\ &= 1 \end{aligned}$$

(the last step follows since $p(v_{i_j}|v^*_{i_{j+1}}) = 0$ if $v_{i_j} \neq v^*_{i_j}$). On the other hand, $p(v^*_{i_1}|z) = p(v^*_{i_1}) = 1/2 \neq 1 = p(v^*_{i_1}|v^*_{i_k}z)$, so $V_{i_1} \rightleftharpoons V_{i_k} \mid Z$, as required. ■

In sum, the constraint graph $\mathcal{G}$ offers a practical representation of the independencies satisfied by the maximum entropy function on account of the structure of the constraint sets.

Let z denote the parameter matrix with rows z_i, for $i = 1, \ldots, m$. Then $(\mathcal{G}, z)$ is called a *Markov network* with respect to the factorisation of Equation 4. Having worked out the values of the constant multipliers $\mu, \lambda_1, \ldots, \lambda_m$ in Equation 4 one can recast the entropy maximisation problem as follows. Given z, one can determine x from the factorisation, and hence the task of finding the x-parameters of the maximum entropy function can be reduced to that of finding the z-parameters of the maximum entropy function. While there were $(\prod_{i=1}^{n} ||V_i||) - 1$ free x-parameters, these are now determined by $\sum_{i=1}^{m}(\prod_{V_j \in C_i} ||V_j||) - 1$ free z-parameters. Note that one would expect the number of values $||V_j||$ that variable V_j can take to be independent of the number of variables n and subject to practical limits. Suppose then that some constant K provides an upper bound for the $||V_j||$. At the end of §3 I suggested that the sizes $|C_i|$ of the constraint sets would also be subject to practical limits: suppose that the $|C_i|$ are bounded above by a constant L. Then there are at most $m(K^L - 1)$ free z-parameters. Thus if the number of constraints m increases linearly with n then so does the number of required z-parameters — a dramatic reduction from the number of x-parameters (bounded above by $K^n - 1$) required under the original formulation of the problem.[12]

[12] In fact, the x-parameters are determined by their marginals on the cliques (maximal complete subgraphs) of $\mathcal{G}$ (see [Lauritzen 1996], page 40). There are at most n cliques, so if clique-size and the $||V_j||$ are bounded above, then the x-parameters are determined by a number of parameters that is *at worst* linear in n.

While the Markov network formulation offers the possibility of a reduction in the complexity of entropy maximisation, it leaves us with two tasks: (i) to find the values of the multipliers in the factorisation, and (ii) to find the values of the z-parameters which yield maximum entropy. Neither of these tasks are straightforward in general: (i) the multipliers must be determined from a system of $\prod_{i=1}^{n} ||V_i||$ equations (one factorisation for each $v@V$), and (ii) the z-parameters must be determined either from the same large system of equations or numerically from an analogue of the large summation expression for entropy, Equation 2.

It is somewhat easier, in fact, to move to a second reparameterisation. Having reduced the complexity of the problem by exploiting independencies, we shall move from a Markov network parameterisation to a Bayesian network parameterisation. This will allow some simplification of the above two tasks and will leave us with a practical representation of the agent's belief function to which standard algorithms for updating can more easily be applied.

5 From Markov to Bayesian Network

An undirected graph is *triangulated* if for every cycle involving four or more vertices there is an edge in the graph between two vertices that are non-adjacent in the cycle. The first step towards a Bayesian network representation of the maximum entropy probability function is to construct a triangulated graph $\mathcal{G}^T$ from the constraint graph $\mathcal{G}$. Of course this move is trivial when, as is often the case, the constraint graph $\mathcal{G}$ is already triangulated. Figure 1, for example, is already triangulated. If $\mathcal{G}$ is not already triangulated, one of a number of standard triangulation algorithms can be applied to construct $\mathcal{G}^T$.[13]

Next, re-order the variables in V according to *maximum cardinality search* with respect to $\mathcal{G}^T$: choose an arbitrary vertex as V_1; at each step select the vertex which is adjacent to the largest number of previously numbered vertices, breaking ties arbitrarily. Let $D_1, \ldots, D_l$ be the cliques of $\mathcal{G}^T$, ordered according to highest labelled vertex. Let $E_j = D_j \cap (\bigcup_{i=1}^{j-1} D_i)$ and $F_j = D_j \backslash E_j$, for $j = 1, \ldots, l$.

In our example involving Figure 1, $V_1, \ldots, V_5$ are already ordered according to a maximum cardinality search,

$$D_1 = \{V_1, V_2\}, D_2 = \{V_2, V_3, V_4\}, D_3 = \{V_3, V_5\},$$

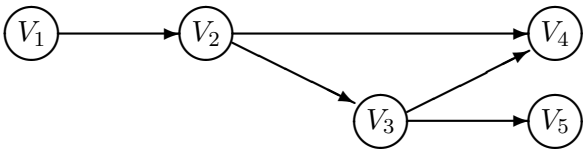
$$E_1 = \emptyset, E_2 = \{V_2\}, E_3 = \{V_3\},$$

$$F_1 = \{V_1, V_2\}, F_2 = \{V_3, V_4\}, F_3 = \{V_5\}.$$

Finally, construct an acyclic *directed constraint graph* $\mathcal{H}$ as follows. Take variables in V as vertices. Step 1: add an arrow from each vertex in E_j to each vertex in F_j, for $j = 1, \ldots, l$. Step 2: add further arrows to ensure that there is an arrow between each pair of

[13] See for example [Neapolitan 1990] §3.2.3 and [Cowell et al. 1999] §4.4.1.

Figure 2: Example directed constraint graph



vertices in $D_j, j = 1, \ldots, l$, taking care that no cycles are introduced (there is always some orientation of an added arrow which will not yield a cycle). In our example, an induced directed constraint graph $\mathcal{H}$ is depicted in Figure 2; the arrow from V_3 to V_4 was the only arrow added in step 2.

For disjoint $X, Y, Z \subseteq V$, Z *D-separates* X from Y in a directed acyclic graph if on each path between X and Y there is a structure $\longrightarrow V_i \longrightarrow$ or $\longleftarrow V_i \longrightarrow$ such that $V_i \in Z$, or a structure $\longrightarrow V_i \longleftarrow$ such that neither V_i nor its descendants are in Z.

Theorem 5.1 If Z D-separates X from Y in the directed constraint graph $\mathcal{H}$ then $X \perp\!\!\!\perp_p Y \mid Z$ for any p satisfying the constraints which maximises entropy.

Proof: Since $\mathcal{G}^T$ is triangulated, the ordering yielded by maximum cardinality search is a *perfect* ordering (for each vertex, the set of its adjacent predecessors is complete in the graph).[14] Because the cliques are ordered according to highest labelled vertex where the vertices have a perfect ordering, the clique order has the *running intersection property* (for each clique, its intersection with the union of its predecessors is contained in one of its predecessors).[15] Now p factorises according to the cliques of $\mathcal{G}^T$, since it factorises according to $C_1, \ldots, C_m$ and these sets are complete in $\mathcal{G}^T$ and so are subsets of its cliques. These three facts imply that $p(v) = \prod_{i=1}^{l} p(f_i^v | e_i^v)$ for each $v@V$, where f_i^v, e_i^v are the assignments to F_i, E_i respectively which are consistent with v.[16]

Take an arbitrary component $p(f_i^v | e_i^v)$ of this factorisation. Each member of E_i is a parent (in $\mathcal{H}$) of each member of F_i and the members of F_i form a complete subgraph of $\mathcal{H}$ so we can write $F_i = \{V_{i_1}, \ldots, V_{i_k}\}$ where the parents of V_{i_j} are $Par_{i_j} =_{df} E_i \cup \{V_{i_1}, \ldots, V_{i_{j-1}}\}$. Hence,

$$\begin{aligned} p(f_i^v | e_i^v) &= p(v_{i_1}^v \ldots v_{i_k}^v | e_i^v) \\ &= \prod_{j=1}^{k} p(v_{i_j}^v | e_i^v v_{i_1}^v \ldots v_{i_{j-1}}^v) \end{aligned}$$

[14] [Neapolitan 1990] Theorem 3.2.
[15] [Neapolitan 1990] Theorem 3.1.
[16] [Neapolitan 1990] Theorem 7.4.

$$= \prod_{j=1}^{k} p(v_{ij}^v | par_{ij}^v)$$

where v_{ij}^v and par_{ij}^v are the assignments to V_{ij}, Par_{ij} respectively that are consistent with v. Furthermore, each variable V_i occurs in precisely one F_j, so

$$p(v) = \prod_{i=1}^{n} p(v_i^v | par_i^v) \tag{5}$$

for each $v \in V$. When Equation 5 holds, p is said to *factorise* with respect to $\mathcal{H}$. It follows by a theorem due to Verma and Pearl that if Z D-separates X from Y in $\mathcal{H}$ then $X \perp\!\!\!\perp_p Y \mid Z$.[17] ■

In general the directed constraint graph $\mathcal{H}$ is not as comprehensive a representation of independencies as the undirected constraint graph $\mathcal{G}$. If $\mathcal{G}$ is not already triangulated then some probabilistic independencies satisfied by entropy maximiser p in virtue of the structure of the constraint sets will not be implied by the directed constraint graph $\mathcal{H}$. To see this note that if $\mathcal{G} \neq \mathcal{G}^T$ then there must be two variables V_i and V_j which are not directly connected in $\mathcal{G}$, and so which are separated by some (possibly empty) Z in $\mathcal{G}$, but which are directly connected in $\mathcal{G}^T$ and thus in $\mathcal{H}$, and which are therefore not D-separated by Z in $\mathcal{H}$. On the other hand if $\mathcal{G} = \mathcal{G}^T$ then we do have an analogue of Theorem 4.2:

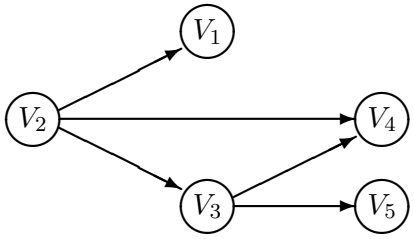
Theorem 5.2 Suppose $\mathcal{G}$ is triangulated. If, for all $\chi_1, \ldots, \chi_m$ constraining $C_1, \ldots, C_m$ respectively, $X \perp\!\!\!\perp_p Y \mid Z$ where p is a function satisfying $\chi_1, \ldots, \chi_m$ that maximises entropy, then Z D-separates X from Y in $\mathcal{H}$.

Proof: To check whether Z D-separates X from Y in $\mathcal{H}$ it suffices to check whether Z separates X from Y in the undirected *moral graph* formed by restricting $\mathcal{H}$ to X, Y, Z and their ancestors, adding an edge between any two parents in this graph that are not already directly connected, and replacing all arrows by undirected edges.[18] But all parents of vertices in $\mathcal{H}$ are directly connected, so the moral graph is a subgraph of $\mathcal{G}^T = \mathcal{G}$. By Theorem 4.2 if $X \perp\!\!\!\perp_p Y \mid Z$ for all such p then Z separates X from Y in $\mathcal{G}$. Hence Z separates X from Y in any subgraph of $\mathcal{G}$ that contains X, Y and Z, and in particular in the moral graph, as required. ■

Given some set $U \subseteq V$ containing V_i and its parents according to $\mathcal{H}$, and $u@U$, define parameter $y_i^u = p(v_i^u | par_i^u)$, where v_i^u, par_i^u are the assignments to V_i, Par_i respectively that are consistent with u. Let y_i be the vector of parameters y_i^u as u varies on V_i and its

[17] See [Neapolitan 1990] Theorem 6.2.
[18] [Cowell et al. 1999] Corollary 5.11.

Figure 3: Alternative directed constraint graph



parents, and let y be the matrix with the y_i as rows, $i = 1, \ldots, n$. In this notation Equation 5 corresponds to

$$x^v = \prod_{i=1}^{n} y_i^v \tag{6}$$

for each $v@V$.

$(\mathcal{H}, y)$ is called a *Bayesian network*. Thanks to the factorisation of Equation 6, the task of finding x-parameters that maximise entropy can be reduced to that of finding the corresponding y-parameters. The number of free y-parameters required is determined by the cliques $D_1, \ldots, D_l$ in $\mathcal{H}$: there are $\sum_{i=1}^{l}(\prod_{V_j \in D_i} ||V_j||) - 1$. Thus if clique-size $|D_i|$ is bounded above by constant R and the number of values $||V_j||$ bounded above by K, there are at most $n(K^R - 1)$ free y-parameters. If $\mathcal{G} \neq \mathcal{G}^T$ then the Bayesian network representation of p will require more parameters than the Markov network representation of §4. However the Bayesian network representation is more convenient for the following reasons.

First, there are no unknown multipliers in Equation 6. In contrast, in order to reconstruct the maximum entropy function from its Markov network representation via Equation 4, the values of constants $\mu, \lambda_1, \ldots, \lambda_m$ must be determined.

Second, the entropy equation can be reformulated in terms of the y-parameters as follows:

$$\begin{aligned}
H &= -\sum_{v@V} x^v \log x^v \\
&= -\sum_{v@V} \left(\prod_{j=1}^{n} y_j^v \right) \log \prod_{i=1}^{n} y_i^v \\
&= -\sum_{v@V} \left(\prod_{j=1}^{n} y_j^v \right) \sum_{i=1}^{n} \log y_i^v \\
&= -\sum_{i=1}^{n} \sum_{v@V} \left(\prod_{j=1}^{n} y_j^v \right) \log y_i^v
\end{aligned}$$

$$= -\sum_{i=1}^{n} \sum_{v@Anc_i} \left(\prod_{V_j \in Anc_i} y_j^v \right) \log y_i^v$$

where $Anc_i \subseteq V$ consists of V_i and its ancestors in $\mathcal{H}$ (other terms cancel in the last step by additivity). In our example, Figure 2 induces an entropy equation of the form

$$H = -\sum_{v@V_1} y_1^v \log y_1^v - \sum_{v@\{V_1,V_2\}} y_1^v y_2^v \log y_2^v - \sum_{v@\{V_1,V_2,V_3\}} y_1^v y_2^v y_3^v \log y_3^v$$

$$- \sum_{v@\{V_1,V_2,V_3,V_4\}} y_1^v y_2^v y_3^v y_4^v \log y_4^v - \sum_{v@\{V_1,V_2,V_3,V_5\}} y_1^v y_2^v y_3^v y_5^v \log y_5^v$$

Note that roughly speaking there are fewest components in the sum of the entropy equation when the sets of ancestors Anc_i are smallest, and that when constructing $\mathcal{H}$, judicious use of maximum cardinality search and orientation of arrows can lead to a directed constraint graph with minimal ancestor sets. In our example, Figure 3 (where the vertices are labelled according to the original ordering, not that given by maximum cardinality search) is an alternative directed constraint graph, which leads to the following entropy equation:

$$H = -\sum_{v@V_2} y_2^v \log y_2^v - \sum_{v@\{V_1,V_2\}} y_1^v y_2^v \log y_1^v - \sum_{v@\{V_2,V_3\}} y_2^v y_3^v \log y_3^v$$

$$- \sum_{v@\{V_2,V_3,V_4\}} y_2^v y_3^v y_4^v \log y_4^v - \sum_{v@\{V_2,V_3,V_5\}} y_2^v y_3^v y_5^v \log y_5^v$$

This version of the entropy equation is more economical in the sense that the largest ancestor sets are smaller than those induced by Figure 2.

Having rewritten the entropy equation in terms of a y-parameterisation one can then use numerical techniques or Lagrange multiplier methods to find the values of the y-parameters that maximise H. If using the latter approach, note that there is an additivity constraint for each $i = 1, \ldots, n$ and each $u@Par_i$, of the form

$$\sum_{v@(\{V_i\} \cup Par_i), v \sim u} y_i^v = 1,$$

and each such constraint will require its own multiplier μ_i^u. Thus for assignment v to V_i and its parents, the partial derivative of the Lagrange equation takes the form

$$\frac{\partial H}{\partial y_i^v} + \mu_i^v + \sum_{i=1}^{m} \lambda_i \frac{\partial f_i}{\partial y_i^v} = 0$$

for

$$\frac{\partial H}{\partial y_i^v} = -\sum_{V_k : V_i \in Anc_k} \sum_{u@Anc_k, u \sim v} \left(\prod_{V_j \in Anc_k, j \neq i} y_j^u \right) [\log y_k^u + I_{k=i}]$$

where $I_{k=i} = 1$ if $k = i$ and 0 otherwise, and where as before $\lambda_i = 0$ for each inequality constraint χ_i which is not effective at y_i^v.[19]

The third advantage of the Bayesian network parameterisation is this: the reparameterisation converts the general entropy maximisation problem into the special case problem of determining the parameters of a Bayesian network that maximise entropy; therefore we can apply existing techniques that have been developed for the special case to solve the general problem. Garside, Holmes, Markham and Rhodes have developed a number of efficient algorithms which determine the parameters of a Bayesian network that maximise entropy. Their approach uses Lagrange multiplier methods on the original version of the entropy equation (Equation 2), subject to the restriction that the constraints be linear functions of the x-parameters. They have also developed specialised algorithms that deal with the cases in which the directed graph in the Bayesian network is a tree or inverted tree.[20] Schramm and Fronhöfer have investigated an alternative solution to the same problem, using an efficient system for maximising entropy that works by minimising cross entropy iteratively.[21]

Fourth, a Bayesian network is a good representation of an agent's belief function, given the uses such a function is normally put to, because Bayesian networks can be amenable to efficient calculations and updating.[22] There is now a large literature and set of computational tools for calculating marginals from a Bayesian network, and in particular conditional probabilities of the form $p(v_i|u)$, where $v_i@V_i$ and

[19] I am grateful to an anonymous referee for posing the following conundrum. Constraints that are linear with respect to the x-parameters may well be non-linear with respect to the y-parameters; can this introduce computational difficulties? The answer is no, in at least two respects. First, if the constraints are linear in the x-parameters then there is a unique function p satisfying the constraints that maximises entropy, and thus unique values for the y-parameters which maximise entropy — we do not need to worry about multiple global maxima. Second, while such a constraint may be a non-linear function of several y-parameters, it is linear when construed as a function of a single specific y-parameter, which is advantageous when using Lagrange multiplier methods for optimisation. Suppose for example we have the constraint χ_1, $p(v_1v_2) - 1 = 0$ which can be written linearly in the x-parameters as $\sum_{v \sim v_1v_2} x^v - 1 = 0$ or non-linearly in the y-parameters as $y_1^{v_1}y_2^{v_1v_2} - 1 = 0$. This constraint is linear when construed as a function of $y_1^{v_1}$ (respectively $y_2^{v_1v_2}$) and thus $\partial\chi_1/\partial y_1^{v_1} = y_2^{v_1v_2}$ does not involve $y_1^{v_1}$. In general, when taking partial derivatives of the Lagrange equation with respect to y_i^v, terms involving y_i^v itself are eliminable. This allows the associated Lagrange multipliers to be determined from other partial derivatives using an inductive process. See §14 of [Williamson 2002] for a detailed account of the use of Lagrange multiplier methods to optimise y-parameters when constraints are linear in the x-parameters.

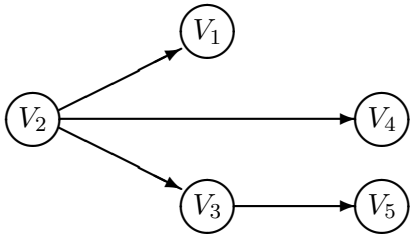
[21] [Schramm & Fronhöfer 2002].

[22] Note that computational efficiency often depends on the structure of the directed graphs in Bayesian networks — very highly connected graphs are often not amenable to fast marginalisation or updating.

Figure 4: Conditional independence constraint incorporated



$u@U \subseteq (V \backslash \{V_i\})$.[23] Many such algorithms also implement Bayesian conditionalisation to update p on evidence u. Bayesian conditionalisation may be generalised to minimum cross entropy updating, which has similar justifications to those of the maximum entropy principle.[24] A minimum cross entropy update of x is a parameter vector x' which minimises

$$d(x, x') = \sum_{v@V} x'^v \log \frac{x'^v}{x^v}$$

subject to any new constraints. By converting this to our y-parameterisation, it is not hard to see that the Bayesian network representation of p' will be the same as the Bayesian network representation of p on all variables except those in the new constraint sets and their predecessors under an ancestral ordering. Numerical methods or Lagrange multiplier methods can then be used with respect to the y-parameter formulation, in order to identify the new Bayesian network representation.[25]

6 Independence and Causal Constraints

Thus far we have been concerned only with the structure of the constraint sets, not with the nature of the constraints themselves. In this section we shall see that certain types of constraints — namely independence constraints and causal constraints — can be treated especially easily, thanks to our Bayesian network representation of the maximum entropy function.

Many conditional independence constraints can be dealt with almost trivially. Suppose that in our example constraint χ_2 on constraint set $\{V_2, V_3, V_4\}$ says that V_3 and V_4 are probabilistically independent conditional on V_2, $V_3 \perp\!\!\!\perp_p V_4 \mid V_2$. Given the Bayesian network representation of Figure 3, this implies that for all assignments $u, v@\{V_2, V_3, V_4\}$ that agree on V_2 and V_4, $y_4^u = y_4^v$. This will hold just when p factorises according to Figure 4. Thus χ_2 can be satisfied just by manipulating $\mathcal{H}$, and changing the parent sets in the

[23] See for example Part 1 of [Jordan 1998] and Chapter 6 of [Cowell et al. 1999].
[24] [Williams 1980].
[25] See [Williamson 2002].

y-parameterisation accordingly — the constraint can then be ignored in the next step of the entropy maximisation process, namely that of finding the values of the new y-parameters that maximise entropy.

Note that it may not always be possible to adjust $\mathcal{H}$ to incorporate independence constraints. If, for example, χ_2 constrains p to satisfy $V_3 \perp\!\!\!\perp_p V_4 \mid V_2$ *and* $V_2 \perp\!\!\!\perp_p V_4 \mid V_3$, then there is no permutation of arrows amongst V_2, V_3, V_4 which will imply both these constraints and no others. The best one can do in this case is incorporate one of the constraints into the graph, and retain the other constraint in the optimisation of the corresponding y-parameters. Note also that if one can only represent a constraint by reversing one or more arrows in $\mathcal{H}$, one must check that the new graph is valid in the sense that there is a maximum cardinality search ordering of the vertices which would yield arrow directions compatible with the new arrow directions.

Causal constraints also have special consequences for entropy maximisation, as we shall see in the remainder of this section.

Judea Pearl articulated two problems with entropy maximisation in his pioneering book on Bayesian networks:

> computational techniques for finding a maximum-entropy [ME] distribution [Cheeseman 1983] are usually intractable, and the resulting distribution is often at odds with our perception of causation.[26]

The first problem — that of computational intractability — may be ameliorated by the methods put forward in the previous sections of this paper. The second problem is that it is counterintuitive that adding an effect variable can lead to a change in the marginal distribution over the original variables:

> For example, if we first find an ME distribution for a set of n variables $X_1, \ldots, X_n$ and then add one of their consequences, Y, we find that the ME distribution $P(x_1, \ldots, x_n, y)$ constrained by the conditional probability $P(y|x_1, \ldots, x_n)$ changes the marginal distribution of the X variables ... and introduces new dependencies among them. This is at variance with the common conception of causation, whereby hypothesizing the existence of unobserved future events is presumed to leave unaltered our beliefs about past and present events. This phenomenon was communicated to me by Norm Dalkey and is discussed in [Hunter 1989].[27]

This problem is exemplified in 'Pearl's puzzle', which Daniel Hunter describes as follows.

> The puzzle is this: Suppose that you are told that three individuals, Albert, Bill and Clyde, have been invited

[26] [Pearl 1988] 463.
[27] [Pearl 1988] 463-464.

> to a party. You know nothing about the propensity of any of these individuals to go to the party nor about any possible correlations among their actions. Using the obvious abbreviations, consider the eight-point space consisting of the events $ABC, AB\bar{C}, A\bar{B}C$, etc. (conjunction of events is indicated by concatenation). With no constraints whatsoever on this space, MAXENT yields equal probabilities for the elements of this space. Thus $Prob(A) = Prob(B) = 0.5$ and $Prob(AB) = 0.25$, so A and B are independent. It is reasonable that A and B turn out to be independent, since there is no information that would cause one to revise one's probability for A upon learning what B does. However, suppose that the following information is presented: Clyde will call the host before the party to find out whether Al or Bill or both have accepted the invitation, and his decision to go to the party will be based on what he learns. Al and Bill, however, will have no information about whether or not Clyde will go to the party. Suppose, further, that we are told the probability that Clyde will go conditional on each combination of Al and Bill's going or not going. ...
>
> When MAXENT is given these constraints ... A and B are no longer independent! But this seems wrong: the information about Clyde should not make A's and B's actions dependent.[28]

To start with, when there are no constraints, the undirected constraint graph on A, B, C has no edges so by Theorem 4.1 the maximum entropy function yields all variables probabilistically independent. However when a constraint involving A, B and C is included, the undirected constraint graph on A, B, C has an edge between each pair of variables. Thus by Theorem 4.2 there is some constraint which renders A and B probabilistically dependent for the maximum entropy function. In fact, as Hunter points out, there is some constraint taking the form of the probability distribution of C conditional on A and B which renders A and B dependent here. But in the context of the above example this constraint seems to provide no information that relates A and B: their dependence does indeed seem counterintuitive here.

The difficulty is that while we have taken into account the probability distribution of C conditional on A and B as a constraint on maximising entropy, we have ignored the further fact that A and B are causes of C. The key question is: how does causal information constrain the entropy maximisation process?

Hunter's answer to this conundrum is that causal statements are counterfactual conditionals and that the constraint in this example

[28] [Hunter 1989] 91.

should be thought of as a set of probabilities of counterfactual conditionals rather than as a conditional probability distribution. Under Hunter's analysis of counterfactuals and probabilities of counterfactuals, a reconstruction of the above example retains the probabilistic independence of A and B when the constraint is added.

Hunter's response is in my opinion unconvincing, for two reasons. First, the counterfactual conception of causal relations adopted by Hunter is problematic. As Hunter himself acknowledges, his possible-worlds account of counterfactuals is rather simplistic.[29] More importantly though, the connection between causal relations and counterfactuals that Hunter adopts is implausible. Hunter says,

> the suggestion is that the relations between Al's and Bill's actions on the one hand and Clyde's on the other are expressible as counterfactual conditionals, that there is a certain probability that if Al and Bill *were* to go to the party, then Clyde *would not* go, and so on. The information to MAXENT should be probabilities of counterfactuals rather than conditional probabilities.[30]

This type of information is written in Hunter's notation using statements of the form $Prob(AB\Box\!\!\rightarrow C) = 0.1$. But such a statement expresses uncertainty about a counterfactual connection: the probability that Clyde would go were Al and Bill to go is 0.1. It does not express what we require, namely certain knowledge about a chancy causal connection, which would be better represented by $AB\Box\!\!\rightarrow (Prob(C) = 0.1)$: if Al and Bill were to go then Clyde would go with probability 0.1. In Pearl's puzzle we are told the exact causal relationships between A, B and C, and Hunter misrepresents these as uncertain relationships. Moreover, correcting Hunter's representation of the causal connections seems unlikely to resolve Pearl's puzzle. In fact depending on how probability is interpreted one can even argue that $AB\Box\!\!\rightarrow (Prob(C) = 0.1)$ if and only if $Prob(C|AB) = 0.1$. For instance, under the Bayesian interpretation of probability $Prob(C|AB) = 0.1$ can be taken to mean that the agent in question would award betting quotient 0.1 to C were AB to occur; under the propensity interpretation it can be taken to mean that AB events have a (counterfactual) propensity to produce C events with probability 0.1. If this equivalence holds then Pearl's puzzle must still obtain, despite the counterfactual analysis.[31]

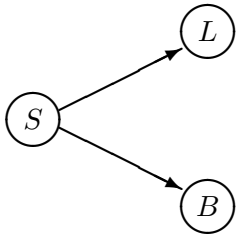
The second difficulty with Hunter's analysis is that while it resolves Pearl's puzzle, it fails to resolve a minor modification of Pearl's puzzle. In the original puzzle we are provided with the probability

[29] [Hunter 1989] 95.

[30] [Hunter 1989] 95.

[31] The relationship between causality and counterfactuals is in fact much more subtle than indicated here — see [Lewis 1973] — and many believe that there is no close relationship on account of these difficulties — see chapters 12-14 of [Sosa & Tooley 1993].

Figure 5: Smoking, lung cancer and bronchitis.



distribution of C conditional on A and B. Suppose instead we are provided with the distribution of C conditional on A, and the distribution of C conditional on B. We then get a puzzle analogous to that of the original problem: there are constraints with respect to which the maximum entropy probability function renders A and B unconditionally dependent. However Hunter's counterfactual reconstruction fails to eliminate the dependence of A and B in this modified puzzle.[32] In defence Hunter argues that his counterfactual analysis warrants the counterintuitive conclusion in the case of the modified puzzle, because according to his analysis situations in which A and B are positively correlated are more probable than situations in which A and B are negatively correlated. However, in the light of the above doubts about Hunter's analysis I suggest that intuition should prevail and that this new puzzle still needs resolving.

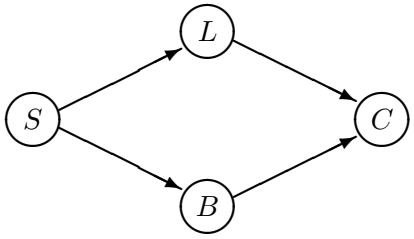
In fact I think that Pearl's puzzle and its modification can be resolved without having to appeal to a counterfactual analysis of causality, any formulation of which is likely to be contentious. The resolution that I propose depends on making explicit the way in which qualitative causal relationships constrain entropy maximisation. Having made this constraint explicit, we shall see that it leads to a general framework for maximising entropy subject to causal knowledge. Finally, at the end of this section we shall see that the framework can be applied to resolve both Pearl's puzzle and its modification.

In [Williamson 2001] I suggested that causality satisfies a fundamental asymmetry, which can be elucidated with the help of the following example. Suppose an agent is concerned with two variables L and B signifying lung cancer and bronchitis respectively. Initially she knows of no causal relationships between these variables, but she may have other background knowledge which leads her to adopt prior probability function p_1. Then the agent learns that smoking S causes each of lung cancer and bronchitis, which can be represented by a directed graph, Figure 5.[33] One can argue that learning of the existence of common cause S should impact on her degrees of belief concerning L and B, making them more dependent. The reasoning is

[32] [Hunter 1989] 101-104.

[33] This graph just represents causal relationships — it should not be interpreted as a representation of probabilistic independencies.

Figure 6: Smoking, lung cancer, bronchitis and chest pains.



as follows: if an individual has bronchitis, then this may be because he is a smoker, and smoking may also have caused lung cancer, so the agent should believe the individual has lung cancer given bronchitis to a greater extent than before — the two variables become dependent (or more dependent if dependent already). Thus p_2, the new probability function determined with respect to her current knowledge (which includes the causal knowledge) might be expected to differ from p_1 over the original domain $\{L, B\}$.

Next the agent learns that both lung cancer and bronchitis cause chest pains C, giving the causal graph of Figure 6. But in this case one can *not* argue that L and B should be rendered more dependent. If an individual has bronchitis then he may well have chest pains, but this does not render lung cancer any more probable because there is already a perfectly good explanation for any chest pains.[34] One cannot reason via a common effect in the same way that one can via a common cause, since learning of the existence of a common effect is irrelevant to an agent's current degrees of belief. Thus the new probability function p_3 ought to agree with p_2 on the domain of p_2, $\{S, L, B\}$.

This central asymmetry of causality can be explicated by what I call the *causal irrelevance* condition. This says roughly that if an agent has initial belief function p_U on domain U and then learns of the existence of new variables which are not causes of any of the variables in U, then the restriction to U of her new belief function p_V on $V \supseteq U$ should agree with p_U on U, written $p_{V\restriction U} = p_U$. This condition can be rendered precise as follows.

Suppose that entropy is to be maximised subject to the causal knowledge represented by directed acyclic causal graph $\mathcal{C}$ on V, as well as the quantitative constraints $\chi = \{\chi_1, \ldots, \chi_m\}$ that we have considered in previous sections. Let $p_{\mathcal{C},\chi}$ denote the probability function that an agent adopts given her knowledge, $\mathcal{C}$ and χ. Given $U \subseteq V$ let $\mathcal{C}_U$ be the graph on U induced by $\mathcal{C}$ (the vertices are variables in U and the arrows correspond to those arrows in $\mathcal{C}$ between variables in U). We shall say that $\mathcal{C}$ is *irrelevant* to U with respect to χ if $p_{\mathcal{C},\chi\restriction U} = p_{\mathcal{C}_U,\chi\restriction U}$, i.e. the information in $\mathcal{C}$ that is not in $\mathcal{C}_U$ has no

[34] This phenomenon is sometimes known as 'explaining away' — see [Wellman & Henrion 1993].

bearing on rational belief over U. A set of variables $U \subseteq V$ is a *ancestral* with respect to $\mathcal{C}$, or $\mathcal{C}$-*ancestral*, if it is closed under parents as determined by $\mathcal{C}$: $V_i \in U \Rightarrow Par_i^{\mathcal{C}} \subseteq U$. The causal irrelevance principle then says:

Causal Irrelevance If U is $\mathcal{C}$-ancestral and $\chi = \chi_U$ involves variables only in U then $\mathcal{C}$ is irrelevant to U with respect to χ_U, i.e. $p_{\mathcal{C},\chi_U|U} = p_{\mathcal{C}_U,\chi_U}$.

My claim is that the causal irrelevance principle captures a key way in which causal knowledge constrains rational belief. Thus it is not enough to maximise entropy subject to quantitative constraints χ: one ought to take qualitative causal knowledge $\mathcal{C}$ into account too, by ensuring that causal irrelevance is satisfied. We shall see shortly how the causal irrelevance principle impinges on entropy maximisation.

First some further explanation of the causal irrelevance principle itself. The requirement that U is ancestral with respect to $\mathcal{C}$ is just the requirement that $V \backslash U$ must not contain any causes of variables in U. In the trivial case in which U is a singleton, $\mathcal{C}_U$ contains no causal information and we set $p_{\mathcal{C}_U,\chi_U} = p_{\chi_U}$, which may be found by maximising entropy subject to χ_U. In general the constraints in χ may involve all variables in V, not just those in U, in which case we can set χ_U to be the subset of those constraints in χ which only involve variables in U, $\chi_U = \{\chi_i : C_i \subseteq U, 1 \leq i \leq m\}$, and apply causal irrelevance to this restricted set of constraints. In this more general case causal irrelevance will tell us that $p_{\mathcal{C},\chi_U|U} = p_{\mathcal{C}_U,\chi_U}$, but nothing about $p_{\mathcal{C},\chi}$ or $p_{\mathcal{C},\chi|U}$. The qualification that χ_U only involves variables in U is important, because knowledge of the existence of an effect together with probabilistic information about the effect itself can provide reason to change the probability distribution over its causes. If an agent with causal knowledge as in Figure 5 learns that lung cancer and bronchitis cause chest pains (Figure 6), *and she learns that the individual in question does have chest pains*, $p(c) = 1$, then arguably her degree of belief that the individual has lung cancer ought to be raised, and so too her degree of belief that he has bronchitis and her degree of belief that he is a smoker. Thus learning of non-causes and their probabilities can provide evidence to change current beliefs.

However, in some situations the probabilistic information about the non-causes $V \backslash U$ does not warrant any change in current beliefs, even when taken in conjunction with new causal knowledge: the new information is irrelevant to beliefs on the current domain U. More precisely we shall say χ is *irrelevant* to U with respect to $\mathcal{C}$ if $p_{\mathcal{C},\chi|U} = p_{\mathcal{C},\chi_U|U}$. For example the constraint $p(c|l \wedge b) = 0.9$ is intuitively irrelevant to $U = \{S, L, B\}$ with respect to $\mathcal{C}$ of Figure 6: learning of probabilities of effects conditional on their causes intuitively should not change degrees of belief over the causes. This intuition generalises as follows:

Probabilistic Irrelevance Suppose χ contains constraints χ_U on U together with constraints of the form $p(s|t) = w$ where $s@S \subseteq V\backslash U$, $t@T \subseteq V$, $w \in [0,1]$. If χ is *compatible* with $p_{\mathcal{C},\chi_U\restriction U}$ in the sense that there is some function p satisfying χ that extends $p_{\mathcal{C},\chi_U\restriction U}$, and U is $\mathcal{C}$-ancestral, then χ is irrelevant to U with respect to $\mathcal{C}$, i.e. $p_{\mathcal{C},\chi\restriction U} = p_{\mathcal{C},\chi_U\restriction U}$.

The compatibility qualification is just a kind of consistency condition: clearly χ can not be irrelevant to U if χ rules out the degrees of belief expressed by $p_{\mathcal{C},\chi_U\restriction U}$.[35] The qualification that U should be ancestral with respect to $\mathcal{C}$ is also required: suppose $\mathcal{C}$ is the graph of Figure 5, $U = \{L, B\}, \chi_U = \emptyset$ but $\chi = \{p(s|l) = 0.99\}$; an agent may plausibly render L and B more probabilistically dependent under $\mathcal{C}$ and χ than under $\mathcal{C}$ and χ_U.

If χ is irrelevant to $\mathcal{C}$-ancestral U with respect to $\mathcal{C}$ then causal irrelevance tells us that

$$p_{\mathcal{C},\chi\restriction U} = p_{\mathcal{C},\chi_U\restriction U} = p_{\mathcal{C}_U,\chi_U} \tag{7}$$

Thus $\mathcal{C}$ and χ are jointly irrelevant to U.

In our example, the agent's belief function with respect to Figure 6 and $\chi = \{p(c|l \wedge b) = 0.9\} \cup \chi_U$ should, when restricted to $U = \{S, L, B\}$, be the same as her original belief function with respect to Figure 5 and original constraints χ_U.

Thus we see that causal irrelevance has practical consequences for rational belief (via Equation 7) just when accompanied by irrelevance of χ with respect to $\mathcal{C}$. This motivates the following recipe for determining exactly how causal knowledge fixes rational belief:

Transfer Suppose χ is irrelevant to $U_1, \ldots, U_k$ with respect to $\mathcal{C}$, where $U_1, \ldots, U_k$ are $\mathcal{C}$-ancestral. Then $p_{\mathcal{C},\chi} = p_{\chi',\chi}$, the probability function p satisfying constraints in χ' and χ which maximises entropy, where $\chi' = \{p_{\restriction U_i} = p_{\mathcal{C}_{U_i},\chi_{U_i}} : i = 1, \ldots, k\}$.

The transfer principle allows us to transfer qualitative causal constraints represented by $\mathcal{C}$ into quantitative constraints χ'. We can determine $p_{\mathcal{C}_{U_i},\chi_{U_i}}$ recursively, and thereby find p by maximising entropy. Noting that the constraint set for constraint $p_{\restriction U_i} = p_{\mathcal{C}_{U_i},\chi_{U_i}}$ is just U_i, we can apply the techniques of §5 to determine a solution.

Let us recap. I have argued that the causal irrelevance condition is a fundamental link between causality and rational belief. However this condition is only useful when accompanied by irrelevance of χ with respect to $\mathcal{C}$ — in which case the transfer principle becomes applicable. Thus the causal irrelevance principle motivates the transfer principle, which in turn offers a practical way to determine the agent's belief function p.

Note that the constraint sets U_i could well be large subsets of V — one would naturally think that this creates a problem for our

[35] See §11 of [Williamson 2002] for more on compatibility.

analysis of §5, which depends on small constraint sets for viability. In fact a bit of further analysis shows that the opposite is the case. Suppose the variables in V are ordered ancestrally with respect to $\mathcal{C}$ (i.e. for each parent V_j of each $V_i, j < i$). Then the Bayesian network representation of $p_{\mathcal{C},\chi}$ is particularly neat when χ is irrelevant to each of $U_i = \{V_1, \ldots, V_i\}$, for $i = 1, \ldots, n$, as we see from the following results.

Theorem 6.1

- Order V ancestrally. Let $U_i = \{V_1, \ldots, V_i\}$ for $i = 1, \ldots, n$.
- Construct directed acyclic constraint graph $\mathcal{H}$ on V by including an arrow to a variable V_i from each predecessor V_j that occurs in some constraint set containing V_i but none of its successors: $V_j \longrightarrow V_i$ iff $j < i$ and $V_i, V_j \in C_k \subseteq U_i$ for some $k, 1 \leq k \leq m$.

If χ is irrelevant to U_i with respect to $\mathcal{C}$ for each $i = 1, \ldots, n$, then

- ▸ Z D-separates X from Y in $\mathcal{H} \Rightarrow X \perp\!\!\!\perp_p Y | Z$ for $p = p_{\mathcal{C},\chi}$.

Proof: By Corollary 3 of [Pearl 1988] it is enough to show that $V_i \perp\!\!\!\perp_p U_{i-1} \mid Par_i^{\mathcal{H}}$ for each $i = 1, \ldots, n$.

Clearly $V_i \perp\!\!\!\perp_{p_{\mathcal{C},\chi}} U_{i-1} \mid Par_i^{\mathcal{H}}$ iff $V_i \perp\!\!\!\perp_{p_{\mathcal{C},\chi|U_i}} U_{i-1} \mid Par_i^{\mathcal{H}}$. Since U_i is ancestral and χ is irrelevant to U_i, we have as in Equation 7 that $p_{\mathcal{C},\chi|U_i} = p_{\mathcal{C}_{U_i},\chi_{U_i}}$ so we need to show that $V_i \perp\!\!\!\perp_{p_{\mathcal{C}_{U_i},\chi_{U_i}}} U_{i-1} \mid Par_i^{\mathcal{H}}$. But this holds as follows. By the transfer principle, $p_{\mathcal{C}_{U_i},\chi_{U_i}} = p_{\chi',\chi_{U_i}}$. $Par_i^{\mathcal{H}}$ is the set of variables in U_i that occur in the same constraints in χ_{U_i} as V_i. Now V_i does not occur in any of the constraint sets of χ', and so $Par_i^{\mathcal{H}}$ is the set of variables in U_i that occur in the same constraints in χ_{U_i} and χ' as V_i. Then applying Theorem 4.1, $V_i \perp\!\!\!\perp_{p_{\chi',\chi_{U_i}}} U_{i-1} \mid Par_i^{\mathcal{H}}$. ■

Note in particular that this directed constraint graph $\mathcal{H}$ corresponding to $p_{\mathcal{C},\chi}$ is no larger (in the sense that it has no more arrows) than the directed constraint graph corresponding to p_χ that would be determined by the techniques of §5.

Thus under the conditions of Theorem 6.1 $(\mathcal{H}, y)$ forms a Bayesian network representation of $p_{\mathcal{C},\chi}$, where the y parameters are defined by $y_i^u = p(v_i^u | par_i^u)$ as in §5. We saw in §5 that in the absence of causal knowledge the y parameters are the parameters that maximise $H = \sum_{i=1}^n H_i$ where

$$H_i = -\sum_{v @ Anc_i} \left(\prod_{V_j \in Anc_i} y_j^v \right) \log y_i^v.$$

However when we have causal knowledge the situation is simpler yet: we can determine the y_1 parameters by maximising H_1, then the y_2 parameters by maximising H_2 subject to the y_1 parameters having been fixed in the previous step, and so on:

Theorem 6.2 Suppose as in Theorem 6.1 that the V_i are ancestrally ordered, χ is irrelevant to each $U_i = \{V_1, \ldots, V_i\}$ with respect to $\mathcal{C}$, and $\mathcal{H}$ contains just arrows to V_i from predecessors that occur in the same constraint set in χ_{U_i}. Then $p_{\mathcal{C},\chi}$ is represented by the Bayesian network $(\mathcal{H}, y)$ where for $i = 1, \ldots, n$ the y_i maximise H_i subject to the constraints in χ_{U_i}.

Proof: We shall use induction on i. For the base case $i = 1$, we proceed as in Equation 7: $y_i^u = p_{\mathcal{C},\chi}(v_1^u) = p_{\mathcal{C}_{U_1},\chi_{U_1}}(v_1^u) = p_{\chi_{U_1}}(v_1^u)$ since the causal knowledge is trivial in this case. This is found by maximising entropy H on domain U_1 subject only to χ_{U_1}, which is just maximising H_1 subject to χ_{U_1}. Assume the inductive hypothesis for case $i-1$ and consider case i. Here we have that $y_i^u = p_{\mathcal{C},\chi}(v_i^u|par_i^u) = p_{\mathcal{C}_{U_i},\chi_{U_i}}(v_i^u|par_i^u)$. We find the y_i^u by maximising H on domain U_i, i.e. $\sum_{j=1}^{i} H_j$, subject to χ_{U_i}. Now the $y_j^u, j = 1, \ldots, i-1$, are fixed by the inductive hypothesis, and hence so are the $H_j, j = 1, \ldots, i-1$. This it suffices to maximise H_i with respect to parameters y_i and subject to χ_{U_i}. ■

Thus when there is causal knowledge and the quantitative knowledge is irrelevant to each $U_i = \{V_1, \ldots, V_i\}$, the general entropy maximisation task, which requires simultaneously finding the y parameters that maximise H, reduces to the simpler task of sequentially finding the y_i parameters that maximise H_i, as i runs through $1, \ldots, n$. Clearly this can offer enormous efficiency savings, both for numerical optimisation techniques and Lagrange multiplier methods. In the Lagrange multiplier case partial derivatives are simpler and each partial derivative involves only one free parameter — in fact it is straightforward to derive an analogue of Equation 4:

$$y_i^v = e^{\frac{\mu_i^v}{\pi} - 1} \prod_{C_i \subseteq U_i} e^{\frac{\lambda_i}{\pi} \frac{\partial f_i}{\partial y_i^v}},$$

where the constant $\pi = \sum_{u @ Anc_i, u \sim v} \prod_{V_j \in Anc_i, j \neq i} y_j^u$ is fixed by having determined y_j^v for $j < i$ earlier in the sequential maximisation.

There is an important special case. Suppose that each variable V_i occurs only with its direct causes $Par_i^{\mathcal{C}}$ in the constraint sets. If χ is irrelevant to each $U_i = \{V_1, \ldots, V_i\}$ then the independence graph $\mathcal{H}$ is just $\mathcal{C}$, the causal graph, and $(\mathcal{C}, y)$ offers a Bayesian network representation of $p_{\mathcal{C},\chi}$.[36]

Suppose for example that all constraints take the form of probabilities of a variable conditional on assignments to their parents. Then compatibility and hence the probabilistic irrelevance of these constraints is guaranteed. If *each* probability of the form $y_i^u = p(v_i^u|par_i^u)$

[36]This analysis can be used to provide an account of when we can expect the *causal Markov condition* to hold. The causal Markov condition says that the independencies implied by a causal graph under D-separation must hold in virtue of the graph being constructed causally. See [Pearl 2000], [Williamson 2001] and [Williamson 2002b] for more on this condition.

is given as a constraint then the probability function $(\mathcal{C}, y)$ is fully determined by the causal graph and the constraints and no work is required to maximise entropy.[37] If some of these parameters are given then sequential maximisation can be used to determine the others.[38]

Another example occurs when background knowledge takes the form of a structural equation model.[39] Such a model can be thought of as a causal graph $\mathcal{C}$ together with, for each variable V_i, an equation $v_i = f_i(par_i, e_i)$ determining the assignment $v_i@V_i$ as a function of assignments par_i to its direct causes Par_i and an assignment e_i to error variable E_i that is not itself a variable in V. Thus for each equation the constraint set consists of V_i and its direct causes. Moreover, these equations are interpreted causally: v_i is fixed by the values of its direct causes; effects do not fix the values of their causes. Under this interpretation constraint equations are irrelevant to $\mathcal{C}$-ancestral sets of variables, since each equation provides information about the effect variable and not its direct causes. Hence the constraint graph $\mathcal{H}$, determined via Theorem 6.1, is just the causal graph $\mathcal{C}$ and by determining y-parameters via Theorem 6.2 we generate a Bayesian network $(\mathcal{C}, y)$ representation of $p_{\mathcal{C},\chi}$, where $\chi = \{v_i = f_i(par_i, e_i) : i = 1, \ldots, n\}$.[40] The y-parameters may be found as follows. Form an extended domain V' which includes the error variables. Then maximise entropy subject to deterministic constraints χ amongst the variables in V'. The Bayesian network representation is trivial to determine: in the independence graph $\mathcal{H}$, the parents of V_i include the error variable E_i as well as the direct causes of $\mathcal{C}$, and each parameter $p(v_i|par_i e_i)$ is 1 or 0 according to whether $f_i(par_i, e_i)$ is v_i or not. Then the y-parameters of the original network V can be determined from this extended network over V' via the identity $p(v_i|par_i) = \sum_{e_i} p(v_i|par_i e_i)p(e_i|par_i) = \sum_{e_i} p(v_i|par_i e_i)p(e_i)$ [since $e_i \perp\!\!\!\perp Par_i$ in the extended network] $= \sum_{e_i} I_{f_i(par_i,e_i)=v_i} p(e_i)$ [where the indicator $I_{f_i(par_i,e_i)=v_i}$ is 1 or 0 according to whether $f_i(par_i, e_i) = v_i$ or not] $= \sum_{e_i} I_{f_i(par_i,e_i)=v_i} 1/||E_i||$ [maximising entropy gives $p(e_i) = 1/||E_i||$ since no constraints convey any information about E_i], and this is just the proportion of assignments e_i to E_i for which $f_i(par_i, e_i) = v_i$.

The situation in Pearl's puzzle resembles the former example. In Pearl's puzzle we are given the causal information $A \longrightarrow C, B \longrightarrow C$, and the conditional probability distribution of C conditional on A and B. By probabilistic irrelevance this conditional probability distribution is irrelevant to $\{A, B\}$ with respect to the causal information. By causal irrelevance the causal knowledge that C is common effect

[37] Thus the approach here generalises that of [Williamson 2001].

[38] This is essentially the context in which [Lukasiewicz 2000] advocated sequential entropy maximisation. The framework here clearly provides a justification for his approach.

[39] [Pearl 2000] §1.4.1.

[40] This provides a justification of the causal Markov condition for structural equation models. The standard justification in this context appeals to a further assumption that error terms are independent — see [Pearl 2000] Theorem 1.4.1.

of A and B is irrelevant to $\{A, B\}$ (with respect to $\chi_{\{A,B\}} = \emptyset$). Our analysis now tells us that the agent's probability function over $\{A, B, C\}$ is represented by a Bayesian network $(\mathcal{C}, y)$, where $\mathcal{C}$ is the graph capturing the causal information and the y-parameters consist of the given conditional distribution together with $p(a) = 1/2$ and $p(b) = 1/2$ found by sequential entropy maximisation. In particular this probability function agrees with that formed on domain $\{A, B\}$ under no constraints. Thus we do not have any puzzling counterintuitive change in degrees of belief.

Moreover, the same reasoning goes through in the modification of Pearl's puzzle. Here we are given the same causal knowledge but the distribution of C conditional on A and that of C conditional on B, not that of C conditional on A and B. We now have to use sequential maximisation to provide the distribution of C conditional on A and B as parameters for a Bayesian network representation, but probabilistic and causal irrelevance still rid us of any counterintuitive dependency between A and B.

7 Maximum Entropy and Probabilistic Logic

The approach developed above has an interesting application to the foundations of probabilistic logic, as we shall now see.

A finite propositional language $\mathcal{L}$ may be thought of as a domain V of n variables $V_1, \ldots, V_n$, each of which is two-valued with possible assignments v_i and $\neg v_i$, for $i = 1, \ldots, n$. The sentences $\mathcal{SL}$ of $\mathcal{L}$ are constructed in the usual manner from these assignments, by applying the connectives $\wedge, \vee, \rightarrow, \leftrightarrow$. The probabilistic sentences $\mathcal{PSL}$ are of the form $p(\theta) = r$, where $\theta \in \mathcal{SL}$ and $r \in [0, 1]$.

The goal of a probabilistic logic is to decide whether and how a probabilistic sentence follows from a set of probabilistic sentences. One attempt at a semantics is to say $p(\theta_1) = r_1, \ldots, p(\theta_m) = r_m \models p(\phi) = s$ iff $p(\phi) = s$ follows by deductive logic from the axioms of probability and the premises $p(\theta_1) = r_1, \ldots, p(\theta_m) = r_m$. This yields rather a weak logic though, in the sense that the premises need not imply $p(\phi) = s$ for any value of s, via the axioms of probability. The premises often *underdetermine* the probability of ϕ.

More interesting, then, is a probabilistic logic with the semantics: $p(\theta_1) = r_1, \ldots, p(\theta_m) = r_m \models p(\phi) = s$ iff $p(\phi) = s$ for a function p, from all those that satisfy the constraints imposed by the premises, that maximises entropy.[41] The constraints imposed by the premises are linear with respect to the x-parameterisation,[42] and so if $\theta_1, \ldots, \theta_m, \phi$ are consistent there is a unique maximum entropy p satisfying the constraints, and thus a unique value s for which

[41] [Nilsson 1986] appears to have been the first to advocate this solution to the problem of probability underdetermination in the context of probabilistic logic. He acknowledges in §5 that his own computational methods become impractical in large problems.

[42] [Paris 1994] pp. 13-14.

$p(\theta_1) = r_1, \ldots, p(\theta_m) = r_m \models p(\phi) = s$.

To complete the logic we require a proof theory such that

$$p(\theta_1) = r_1, \ldots, p(\theta_m) = r_m \vdash p(\phi) = s$$

if and only if

$$p(\theta_1) = r_1, \ldots, p(\theta_m) = r_m \models p(\phi) = s.$$

We can apply the methods developed in preceding sections to develop such a proof theory. These methods give a practical procedure for finding the value of $p(\phi)$ for maximum entropy p, given the constraints $p(\theta_1) = r_1, \ldots, p(\theta_m) = r_m$. We can then compare this value with s in order to decide the probabilistic consequence.

In this case the constraint sets C_i are the variables whose assignments occur in θ_i, for $i = 1, \ldots, m$. We construct a Bayesian network that represents the maximum entropy probability function p using the procedure outlined in §5. Let V_ϕ be the variables whose assignments occur in ϕ. Note that $p(\phi) = \sum_{v@V_\phi, v\models\phi} p(v)$. Thus by querying the Bayesian network to find these $p(v)$ one can determine the correct value for s. If few variables occur in each θ_i in comparison with n as n becomes large then the constraint sets will be small relative to n, the induced Bayesian network correspondingly sparse, and the querying for $p(v)$ correspondingly quick.

We have, then, a fully general proof procedure for probabilistic logic which promises to be practical for a range of problems.[43] While our techniques for maximising entropy efficiently were developed for simple domains of finitely-many finitely-valued variables, they can be applied to quite complex problems, such as reasoning under uncertainty about sentences of logical languages.

8 Concluding Remarks

Merely given the sets of variables that feature in constraints imposed by background knowledge one can achieve significant reductions in the number of parameters required to specify a maximum entropy probability function. I have described two representations of the maximum entropy function — a Markov network and a Bayesian network representation. A Markov network offers a natural representation of the independencies determined by the constraint sets, while a Bayesian network captures many if not all of these independencies and moreover offers a useful factorisation in terms of conditional probabilities of variables given their parents.

The approach presented here is perhaps best viewed as an extension or enhancement of, rather than an alternative to, several of the

[43] For an in-depth discussion of the foundations of probabilistic logic see [Williamson 2002c]. [Lukasiewicz & Kern-Isberner 1999] discusses maximum entropy applied to probabilistic logic programming.

other proposed solutions to the entropy maximisation problem. First, as noted earlier, simple numerical or Lagrange multiplier techniques can be very inefficient when directly applied to entropy maximisation in its standard parameterisation. However, by applying these methods to the Bayesian network parameterisation, dramatic efficiency savings can be made.[44] Second, the approach presented here can be viewed as an extension of the entropy maximisation techniques of Garside, Holmes, Markham and Rhodes, and of Schramm and Fronhöfer, from Bayesian networks to the general case. Third, Cheeseman presented a method for exploiting the log-linear factorisation of the maximum entropy function to compute conditional probabilities more efficiently,[45] and the present approach takes this a step further by enabling all the machinery developed for calculating conditional probabilities from Bayesian networks to be directly applied to the maximum entropy function.[46]

I have argued that the reparameterisations are most useful when the constraint sets are small in comparison with n, as n grows. I suggested that small constraints sets are the norm, but I have made no attempt to analyse their ubiquity here. This is an empirical claim and some form of empirical testing of this claim, as well as an empirical analysis of the practical performance of the reparameterisation approach, would clearly be of interest as the next step in developing this research. It remains to be seen whether small constraint sets are predominant in applications of probabilistic logic, and in other specialised applications of maximum entropy reasoning such as communication theory[47] and statistical physics.[48] Note that natural language processing has recently become an important application domain for maximum entropy techniques.[49] In natural language processing one often considers constraints imposed by context on the meaning of terms.[50] The number of context variables that can be

[44]Of course in certain situations the problem may be simple enough not to warrant reparameterisation. If there are a small number of linear constraints, for example, then Lagrange multiplier methods can be used quite efficiently by converting to unconstrained dual form and optimising with respect to the multipliers as parameters.

[45][Cheeseman 1983].

[46]Note that while Goldman and Rivest also build on Cheeseman's approach and also construct graphs as part of the entropy maximisation process ([Goldman & Rivest 1986], [Goldman & Rivest 1988]), their resulting proposal is quite different from the one presented here: they restrict attention to the case in which constraints are marginal probabilities; they construct a hypergraph (a graph involving sets of variables as vertices) and suggest the collecting of new data, and thus new constraints, in order to make the hypergraph acyclic; when this is achieved, the maximum entropy function can be calculated from the marginal constraints.

[50]Here the context of a term is taken to include its surrounding terms and

considered in these constraints is not fixed in advance but is dictated by available computational power. By pursuing a Bayesian network parameterisation, one may therefore be able to increase the size of the contexts that can be used to ascertain meaning.

It would also be interesting to look more closely at implementational issues. We have seen, for instance, that different maximal cardinality search orderings will yield different directed constraint graphs from the same undirected constraint graph, some of which lead to an entropy equation with fewer terms: is there a way of quickly identifying an optimal directed constraint graph? A variety of numerical techniques are used for maximising entropy with respect to the standard parameterisation:[51] how do they compare on the Bayesian network parameterisation? How do Lagrange multiplier methods fare on the Bayesian network parameterisation?

While several questions remain open, I hope to have shown here that the construction of a Bayesian network from constraints offers the prospect of efficient entropy maximisation.
